ABSTRACT

The RXTE satellite observed the Coma cluster for ~ 177 ks during November and December 2000, a second observation motivated by the intriguing results from the first ~ 87 ks observation in 1996. Analysis of the new dataset confirms that thermal emission from isothermal gas does not provide a good fit to the spectral distribution of the emission from the inner 1° radial region. While the observed spectrum may be fit by emission from gas with a substantial temperature gradient, it is more likely that the emission includes also a secondary non-thermal component. If so, non-thermal emission comprises $\sim 8\%$ of the total 4–20 keV flux. Interpreting this emission as due to Compton scattering of relativistic electrons (which produce the known extended radio emission) by the cosmic microwave background radiation, we determine that the *mean, volume-averaged* magnetic field in the central region of Coma is $B \sim 0.1 - 0.3 \mu\text{G}$.

Subject headings: Galaxies: clusters: general — galaxies: clusters: individual (Coma) — galaxies: magnetic fields — radiation mechanisms: non-thermal

1. Introduction

X-ray spectra of clusters of galaxies have long been expected to show structure beyond that of a single temperature thermal model, mainly due to non-isothermality of intracluster (IC) gas in the outer cluster region. In addition, non-thermal (NT) X-ray emission in clusters was predicted (*e.g.*, Rephaeli 1977) from Compton scattering of relativistic electrons by the Cosmic Microwave Background (CMB) radiation. There is at least some observational evidence for radial variation of the gas temperature in a few clusters (*e.g.*, Markevitch 1996, Honda *et al.* 1996, Donnelly *et al.* 1999, Watanabe *et al.* 1999). In the Coma cluster, recent XMM measurements indicate (Arnaud *et al.* 2001) that the temperature is remarkably constant within the central region where temperature variation was previously deduced from ASCA measurements. After a long search (for a recent review, see Rephaeli 2001), NT X-ray emission seems to have finally been measured in Coma (Rephaeli, Gruber & Blanco 1999, hereafter RGB, Fusco-Femiano *et al.* 1999), A2256 (Fusco-Femiano 2000), A2319 (Gruber & Rephaeli 2002), and perhaps also in A2199 (Kaastra *et al.* 2000).

Appreciable deviation from isothermality may have significant impact on modeling the structure and evolution of IC gas, and on use of the gas as a probe to determine the total cluster mass (assuming hydrostatic equilibrium). The exact gas density and temperature profiles are also very much needed in analysis of measurements of the Sunyaev-Zeldovich (S-Z) effect and its use as a cosmological probe. There clearly is strong motivation for a more realistic characterization of cluster X-ray spectra for an improved description of IC gas, and the study of NT phenom-

ena in clusters.

We have previously analyzed ~ 87 and ~ 160 ks RXTE measurements of the Coma cluster and A2319, respectively, in order to search for NT emission from these clusters which have well documented extended regions of radio emission. Analyses of these measurements yielded strong evidence for a second spectral component in both clusters. While the second component could possibly indicate a temperature variation across the cluster, we have concluded (RGB, Gruber & Rephaeli 2002) that the deduced spectral parameters are more consistent with power-law emission. NT emission in Coma seems to have been detected directly – in the 25-80 keV range – by BeppoSAX (Fusco-Femiano *et al.* 1999). This provided further impetus to propose a longer observation of this cluster with RXTE. Here we briefly report the results from a joint analysis of these and the previous RXTE measurements, with a total integration time of ~ 264 ks, and discuss some of their direct implications.

2. Observations and Data Reduction

Coma was observed with the Proportional Counter Array (PCA) and the High Energy X-ray Timing Experiment (HEXTE) on RXTE during 58 separate pointings totaling approximately 87 ks in June 10 – 22, and July 15, 1996, and during 50 additional pointings totaling nearly 177 ks in November 24 – December 15, 2000. Spectral results from the earlier observation were reported by RGB.

PCA data were collected in the ‘Standard 2’ spectral mode, which consists of a 129-channel count spectrum nominally spanning 2 to 1000 keV with 16 second time resolution. Data from the two independent HEXTE clusters of detectors were taken in event-by-

event mode, which were subsequently accumulated into 256-channel spectra spanning 17–250 keV. To subtract the background, each HEXTE cluster was commanded to beam-switch every 16 s or 32 s between on-source and alternate off-source positions 1.5° on either side.

Standard screening criteria were applied to the data segments (Earth elevation angle, spacecraft pointing, avoidance of the South Atlantic Anomaly, times of geomagnetic activity), resulting in a net exposure time for PCA of 87328 s during the 1996 observations and 176864 s during the second observation set. During the first set of observations PCA detectors 0, 1 and 2 were always on, but detectors 3 and 4 were enabled for less than half of the observation set, and were ignored in the interest of a more uniform data set. The (year) 2000 observations were made with PCA detectors 0 and 2 only, but the detector 0 spectra could not be used because of the loss of the guard propane layer, resulting in higher and uncertain background. The detector 2 gain was about 10% higher in the later observations. The HEXTE data, by contrast, formed a perfectly uniform data set, with no changes of number of detectors or gain. HEXTE net times were shorter than PCA by nearly a factor of four: half the time was used for background measurement, and nearly another factor of two was lost due to electronic dead time caused by cosmic rays.

The PCA background was estimated with the ‘L7/240’ faint source model provided by the instrument team. No significant emission from Coma was detected above $\sim 40 - 50$ keV. The spectral data above 40 keV were used to determine a correction of $\sim 0.5\%$ to the background estimate. No such tuning was required for the HEXTE background, which

is measured, and has been determined (MacDonald 2000) to be accurate to within a few hundredths of a count/s in long exposures.

3. Spectral Analysis

At about 40 count/s per PCA detector, the observed counting rate from Coma was well above the background rate of 13 count/s per detector, thus the cluster was easily detected and possible errors of background estimation are unlikely to compromise spectral analysis. The HEXTE net rate of somewhat less than one count/s per cluster was well below the background rate of 80 counts/s per cluster but still large compared to the error limit of roughly 0.03 counts/s determined by MacDonald (2000). Inspection of the screened light curves for PCA and HEXTE revealed no significant variation, as expected for a cluster of galaxies. Accordingly, we co-added all the selected PCA and HEXTE data to form net spectra for analysis. Spectra from the individual PCA detectors were also coadded, and the small differences in gain were accounted for in the generation of the energy response matrices, following procedures prescribed by the PCA analysis team.

A small energy dependence for systematic errors (e.g., Gruber et al 2001, Wilms et al. 1999) averaging about 0.3%, was applied to the PCA spectrum. Additionally, PCA spectral channels below 4 keV and above 22 keV were excluded because of sensitivity to artifacts in the background model, as well as the rapidly declining effective area of the PCA outside these bounds. The HEXTE data were restricted to the energy range 19–80 keV for similar reasons, resulting in source and background counting rates of 0.75 and 84.1 count/s respectively (cluster A), and 0.49 and 58.1 count/s (cluster B).

Repeating the procedure in RGB, we fit the joint PCA and HEXTE spectra summed over all observations to three simple spectral models: a Raymond-Smith (R-S) thermal plasma emission model, R-S plus a power law model, and two R-S models at different temperatures. In all three cases most of the observed flux is in a primary ~ 8 keV R-S component. Best-fit parameters and 90% confidence intervals are listed in Table 1. The best-fit temperature in the single isothermal gas model is 7.90 ± 0.03 keV, in good agreement with the range determined from ASCA measurements (Honda *et al.* 1996), and only $\sim 4\%$ less than the value of 8.2 keV deduced recently from XMM measurements of the *central 10'* region of Coma (Arnaud *et al.* 2001). This region is much smaller than the RXTE $\sim 1^\circ$ field of view. The observed $\simeq 6.7$ keV Fe XXV K_α line yields an abundance of 0.195 ± 0.008 (in solar units), quite consistent with previously determined values (≥ 0.2). No cold absorption was measurable, and given the 4 keV PCA threshold, none was expected.

The poor quality of the fit to a single isothermal model is apparent from the fact that $\chi^2 = 76.8$ for 45 degrees of freedom. Residuals have a high-low-high pattern which signals the need for another smooth spectral component. When a second thermal component is added, best-fit parameters are $kT_1 \simeq 7.5$ keV, and a very high $kT_2 \simeq 37.1$ keV, with the second component accounting for a modest fraction, $\sim 6\%$ of the total flux. For this fit, $\chi^2 = 48.1$, lower by 28.8 than the value obtained in the single R-S model. The F-test probability of the second component is 0.9992 for two additional degrees of freedom. The range of solutions is very large, however, because the problem is numerically highly degenerate. If we consider the possible

sets of (kT_1, kT_2) , the contour $\chi^2 + 4.6$ defines the joint 90% probability contour. The lowest temperature combination permitted in this range is $kT_1 = 5.48$ keV and $kT_2 = 9.0$ keV, with fractions of the 4–20 keV flux, respectively, of 24% and 76%. The highest temperature combination has $kT_1 \simeq 7.5$ keV and kT_2 unbounded. Equal 4–20 keV flux contributions are obtained with the values 6.5 and 10.5 keV for the two temperatures.

A somewhat better fit than the two-temperature model, $\Delta\chi^2 = 30.7$ (with respect to the single R-S model), is obtained when the second component is a power-law, with a photon index of 2.1 ± 0.5 (90% confidence). The 4–20 keV flux of the power-law component is 8% of the total. This component comprises most of the flux only at energies ≥ 60 keV. The iron abundance changes negligibly from the value obtained with the isothermal fit. The count rate from the combined thermal and power-law emissions, and that of just the power-law component, are shown in Figure 1, together with the measurements.

Only very limited comparisons can be made with other satellite measurements due to differences in spectral bands and field of views. Using archival ASCA GIS spectra of the central 20' diameter region of Coma, we find that these are well fit by a single temperature Raymond-Smith model, with $\chi^2 = 664$ for 713 degrees of freedom. However, fitting an extra power law component with number index 2.3 reduces χ^2 by 12, and thus is significant at about the 3σ level. The 3–10 keV band common to both ASCA and RXTE is most useful for comparison: the ASCA power law represents 5 ± 2 percent of the total emission, consistent at 68% with the corresponding RXTE value of 7%.

EUV emission from the Coma cluster was

Table 1: Results of the spectral analysis

Parameter	single R-S	two R-S	R-S+power-law
χ^2/dof	76.8/45	48.1/43	46.1/43
kT_1 (keV)	7.90 ± 0.03	7.47 ± 0.22	7.67 ± 0.1
Normalization ^a	0.348 ± 0.002	0.345 ± 0.020	0.334 ± 0.016
Abundance ^b	0.195 ± 0.008	0.192 ± 0.010	0.202 ± 0.017
kT_2 (keV)		37 ± 29	
Normalization ^a		0.011 ± 0.011	
$I_e(5 \text{ keV}) (cm^{-2} s^{-1})$			$(3.3 \pm 1.0) \times 10^{-4}$

^ae.m. = Raymond-Smith emission measure in units of $10^{-14} \int N_e N_H dV / 4\pi D^2$, where D is the luminosity distance and N_e , N_H are the total number of electrons and protons, respectively.

^bAbundance is expressed relative to solar values.

measured with the EUVE by Bowyer & Berghofer (1998). The emission is said to be at a level significantly higher than what is expected from the main X-ray emitting gas, and presumably cannot be explained simply by invoking a second, colder, $T \sim 10^6$ K, gas component. A similar conclusion was recently reached by Durret *et al.* (2002) from re-analysis of EUV and ROSAT measurements.

A more direct comparison of our spectral results can be made with BeppoSAX observations of Coma with the MECS and PDS experiments. Analysis of the PDS measurements led Fusco-Femiano *et al.* (1999) to conclude that a significant (at the 4.6σ level) NT flux, $2.2 \times 10^{-12} \text{ ergs cm}^{-2} \text{ s}^{-1}$, was detected at energies 20–80 keV. While this range includes the values we inferred from the RXTE measurements, it should be noted that an accurate spectral analysis of the combined MECS and PDS data is not possible because of the very different fields of view of these experiments.

4. Discussion

The consistent results from the analysis of the second (year 2000) and combined (years 1996 & 2000) datasets further substantiate the reality of the detection of a second component in the Coma spectrum. If thermal, this component could help determine the thermal structure of IC gas, which in turn would have important implications for the use of clusters as cosmological probes in general, and the most extensively researched nearby rich cluster in particular. If this component is NT emission from a population of relativistic electrons, then a new dimension for the study of NT IC phenomena will have been opened. Since the combined ~ 264 ks RXTE observations have not yielded direct detection of power-law emission at energies > 30 keV, we have to invoke other observational and theoretical considerations in order to identify more uniquely the origin of the extra emission we have deduced.

It is unrealistic to expect that IC gas is

Fig. 1.— The RXTE (photon) spectrum of the Coma cluster and folded Raymond-Smith ($kT \simeq 7.67$), and power-law (index = 2.3) models. HEXTE data points are marked with circles and 68% error bars. The total fitted spectrum is shown with a histogram, while the lower histogram shows the power-law portion of the best fit. The quality of the fit is demonstrated in the lower panel, which displays the observed difference normalized to the standard error of the data point.

fully isothermal outside the central region of the cluster. A more likely behavior is at least some decrease of the temperature outside a central $\sim 2 - 3$ core radii region. Indeed, previous ASCA measurements of Coma (Honda *et al.* 1996) and other clusters (e.g., Markevitch 1996) seem to have shown some deviations from isothermality. In Coma, the Honda *et al.* (1996) analysis of measurements from 14 different pointings of an area extending $\sim 1^\circ$ from the center indicated that the IC gas temperature varied by $\pm 50\%$ – with respect to the overall mean value of ~ 8 keV – in two azimuthal regions $40'$ from the center. However, these two regions cover only a small part of the projected area of the cluster, and since the temperature is higher than the mean in one region, while it is lower in the other, the overall change of the spectral flux, as compared with that from an isothermal gas at the mean cluster temperature, is negligible. More recent results from high spectral and spatial resolution measurements of Coma with XMM it was concluded that the temperature is constant in the central $\sim 10'$ radial region, with a best fit value of 8.2 ± 0.1 keV (Arnaud *et al.* 2001). While the fits to the XMM data do not seem to have included two-temperature models, it is clear that an appreciable emission at a significantly different temperature than this mean value would have been deduced from the XMM measurements through a larger variance, if not in the form of a systematic temperature gradient.

The results of our RXTE analysis yield a statistically most probable temperature combination with a prohibitively high value for the second component, $kT_2 \simeq 37.1$. At its lowest boundary, the 90% contour region in the (kT_1, kT_2) plane does include the more acceptable values $kT_1 = 5.5$ keV, and $kT_2 = 9$,

but this only if the respective 4–20 keV fractional fluxes of these two components are 24% and 76%. It is quite unlikely that about a quarter of the flux could come from a component with a significantly lower temperature than the mean value deduced by virtually all previous X-ray satellites. In particular, such a component would have been detected in the high spatially resolved measurements with ROSAT and XMM.

To assess the possibility that a two-temperature gas model is just a simplified representation of a more realistic continuous temperature distribution, we have repeated the following simple procedure we employed in our analysis of the first RXTE observations (RGB): Assuming a polytropic gas temperature profile of the form $T(r) \propto n(r)^{\gamma-1}$, with the familiar β density profile for the gas density, $n(r) \propto (1 + r^2/r_c^2)^{-3\beta/2}$, where r_c is the core radius, we calculated the integrated flux and the mean emissivity-weighted temperatures as functions of γ , β , and r . These quantities were then calculated in the regions $[0, r]$ and $[r, R_0]$ by convolving over the triangular response of the PCA with $R_0 \simeq 58'$. From ROSAT observations, $r_c \sim 10.0'$, and $\beta \simeq 0.70 \pm 0.05$ (Mohr *et al.* 1999). We sought the range of values of r , β , and γ for which the two mean emissivity-weighted temperatures and respective fluxes from these regions are closest to the values deduced from our spectral analysis in Section 3. The results of these calculations indicate that for $0.5 \leq \beta \leq 0.9$ and $1 \leq \gamma \leq 5/3$, there is no acceptable polytropic configuration that matches the observationally deduced values of the temperatures and fractional fluxes. For low values of γ the temperature gradient is too shallow, while for high values the implied central temperature is unrealistically high. This simple plausibil-

ity check suggests that the two thermal components model is somewhat inconsistent with the RXTE results. However, the gas distribution may be more complicated than considered here, so that a temperature structure as implied here cannot be altogether ruled out.

Of particular interest is the somewhat more likely possibility that the secondary spectral component is NT. Since emission from an AGN in the FOV is not likely (see details in RGB), it is natural to consider that this emission is due to Compton scattering of relativistic electrons whose presence in Coma is directly inferred from many measurements of spatially extended region of radio emission (*e.g.*, Kim *et al.* 1990, Giovannini *et al.* 1993). From the measured radio spectral index, 1.34 ± 0.1 , it readily follows that the predicted power-law (photon) flux from Compton scattering of these electrons by the CMB has an index 2.34 ± 0.1 , a value which is quite consistent with what we have inferred, 2.1 ± 0.5 (all errors are at 90% confidence). With the measured mean radio flux of 0.72 ± 0.21 Jy at 1 GHz, the power-law X-ray flux deduced here, and the *assumption* that the spatial factors in the theoretical expressions for the two fluxes are roughly equal, we can easily compute (see more details in RGB) the mean volume-averaged value of the magnetic field, B_{rx} . Taking into account the full 90% range of values of the radio flux, radio index, and the power-law X-ray flux, we get $B_{rx} \simeq 0.1 - 0.3 \mu\text{G}$. This range of values for B_{rx} is consistent with our previous estimate (RGB), and the range (0.14 - 0.25 μG) deduced by Fusco-Femiano *et al.* (1999).

Since we have assumed that the spatial factors in the theoretical expressions for the radio and NT X-ray fluxes are roughly equal, it follows that the mean value of the deduced

magnetic field is independent of the source size and distance. To determine the relativistic energy density we do have to specify the radius of the emitting region. Scaling to the observed radius of the diffuse radio emission, $R \sim 20'$, and integrating the electron energy distribution over energies in the observed radio and X-ray bands, we obtain $\rho_e \simeq (8 \pm 3) \times 10^{-14} (R/20')^{-3} \text{ erg cm}^{-3}$; a distance of 139 Mpc (with $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$) was used. Based on the high Galactic proton to electron energy density ratio of cosmic rays, it can be conjectured that the energetic proton energy density is considerably higher than this value.

The strength of IC magnetic field can also be estimated from Faraday rotation measurements of background radio sources seen through clusters, yielding a different mean field value, B_{fr} . Analyses of such measurements usually yield field values that are a few μG (see, *e.g.*, Clarke, Kronberg, and Böhringer 2001, and the review by Carilli & Taylor 2002). Clearly, the mean strength of IC fields has direct implications on the range of electron energies that are deduced from radio measurements, and therefore on the electron (synchrotron and Compton) energy loss times. Higher electron energies imply shorter energy loss times, with possibly important ramifications for relativistic electron models (*e.g.*, Rephaeli 1979, Sarazin 1999, Ensslin *et al.* 1999, Brunetti *et al.* 2001, Petrosian 2001).

Much has been written about the apparent discrepancy between deduced values of B_{rx} and B_{fr} . Indeed, it is sometimes claimed that this discrepancy makes Compton interpretation of cluster power-law X-ray emission untenable. However, B_{rx} and B_{fr} are actually quite different measures of the field: Whereas the former is essentially a volume average of

the relativistic electron density and (roughly) the square of the field, the latter is an average of the product of the line of sight component of the field and gas density. All these quantities vary considerably across the cluster; in addition, the field is very likely tangled, with a wide range of coherence scales which can only be roughly estimated. These make the determination of the field by both methods considerably uncertain. Thus, the unsatisfactory observational status (stemming mainly from lack of spatial information) and the intrinsic difference between B_{rx} and B_{fr} , make it clear that these two measures of the field cannot be simply compared. Even ignoring the large observational and systematic uncertainties, the different spatial dependences of the fields, relativistic electron density, and thermal electron density, already imply that B_{rx} and B_{fr} will in general be quite different. This was specifically shown by Goldshmidt & Rephaeli (1993) in the context of reasonable assumptions for the field morphology, and the known range of IC gas density profiles. It was found that B_{rx} is typically expected to be smaller than B_{fr} . Various statistical and physical uncertainties in the Faraday rotation measurements, and their impact on deduced values of IC fields, were investigated recently by Newman, Newman & Rephaeli (2002); their findings further strengthen the assessment that a simple minded comparison of values of B_{rx} and B_{fr} is meaningless, and that it is quite premature to draw definite conclusions from the apparent discrepancy between values deduced by these very different methods to measure IC magnetic fields.

As we have mentioned in the previous section, the excess EUV emission in Coma could also be NT, and based on the similar morphologies of the EUV emission and low fre-

quency radio emission, Bowyer & Berghofer (1998) interpreted this emission as Compton scattering of the CMB by a population of low energy electrons. They adopted a value for the power-law index which is somewhat lower than the value used here, but deduced a similar value ($\sim 0.2 \mu\text{G}$) for the mean magnetic field. More recently, Tsay, Hwang & Bowyer (2002) have explored whether a Compton origin for the observed EUV excess can be maintained even if the field is as high (few μG) as is currently deduced from Faraday rotation measurements. They conclude that this is possible within a limited class of lower energy ($\sim 100 \text{ MeV}$) NT electron models, and that in this case a different (second) population of relativistic electrons is required to explain the measurements of NT X-ray emission by RXTE and BeppoSAX. Note that significant IC density of sub-relativistic electrons could in principle also produce high energy X-ray emission by NT bremsstrahlung (Kaastra *et al.* 1998, Sarazin & Kempner 2000). However, the properly normalized contribution of such electrons to the power-law emission deduced here from the RXTE measurements is too small (Shimon & Rephaeli 2002) to affect our estimated value of the magnetic field.

Further evidence for the NT nature of the second spectral component in Coma could possibly come from the scheduled 500 ks observation of this cluster with with IBIS imager aboard the INTEGRAL satellite. The moderate $\sim 12'$ spatial resolution of IBIS can potentially yield crucial information about the location and size of high energy NT X-ray emission.

We are grateful to the referee for useful comments made on an earlier version of the paper.
